(Hepple, 1971). This occurred because hydrocarbon dispersion rather than the oxygen-dissolution rate was the factor limiting microbial growth in the petroleum degradation process (Blakebrough *et al.*, 1967). The high mixing-energy required for the treatment of industrial waste-water is more likely to create a larger substance–water interface for the microorganisms.

MECHANISM OF BIODEGRADATION

By using a specific strain of PCB-degrading Bacteria, which had been isolated from sewage sludge and examined with both light and scanning electron microscopes, it has been possible to show that the primary site of PCB-biodegradation is actually the PCB–water interface. This initial PCB–water interfacial area is the true microbial growth-limiting factor which governs the subsequent rate of PCB degradation. In order to accelerate the rate of PCB biodegradation, sufficient PCB–water interfacial area must be provided at an early stage in the microbial growth-medium to supply sufficient accessible substrate to the microorganisms. This is accomplished by using ultrasonification to make a fine emulsion of PCBs and then having the emulsion stabilized by addition of lignin derivatives, such as lignin sulphonate. By using this new technique, a highly chorinated biphenyl, such as Aroclor 1254, can be reduced in one week from concentrations of 300,000 ppb to little more than 20 ppb. The presence of other nutrient organic compounds, such as glucose and sodium acetate, did not interfere with the rate of PCB degradation by these substrate-specific Bacteria. Moreover, these Bacteria could oxidize PCBs over a wide range of temperature (4° to 35°C).

This discovery is likely to be most applicable in the treatment of industrial wastes containing PCBs. Although it may not answer the problem of PCBs that are already dispersed in the environment, the new technique may have some application in the treatment of various other toxic organic compounds. I hope this short paper will serve to open up a possible new approach to our understanding of the mechanism of the biodegradation of persistent toxic organic substances in the environment.

ACKNOWLEDGEMENTS

The author is grateful to Drs D. B. Cohen and P. G. Sly for their critical reviewing of this paper.

SUMMARY

The failure of conventional waste-treatment methods to solve problems associated with complex industrial wastes, suggests that we must re-examine our approach to this problem. Two distinct types of biodegradation, homogeneous and heterogeneous, have been recognized to occur in the environment and are distinguished according to the solubility or insolubility, respectively, of the compound involved. Unfortunately, many of the most persistent toxic compounds fall into the second or insoluble category, and conventional treatment processes are inefficient in dealing with them.

Our studies have shown that the primary site of the biodegradation of these persistent compounds is at the substance–water interface and that the rate of such biodegradation can be greatly increased if the tested compound can be suspended in an aqueous phase as a fine stable emulsion. Our recent work on PCB biodegradation exemplifies the benefit of a multidisciplinary approach in solving environmental problems, and supports the need to continue fundamental research in such areas of applied environmental science.

Seychelles Asked to Continue Marine Turtle Protection

The Seychelles Government has been asked not to yield to pressure to relax protection of the endangered Green Turtle (*Chelonia mydas*). The World Wildlife Fund (WWF) and the International Union for Conservation of Nature and Natural Resources (IUCN), in a joint cable to the Hon. James R. M. Mancham, Chief Minister of Seychelles, referred to reports of strong pressure to drop protection. They said an extensive survey was needed before any such steps were taken and accordingly promised their aid.

The Green Turtle is among the most widely distributed of the seven existing species of marine turtles, all of which are in danger of extinction because of excessive exploitation of females and their eggs, which they lay on tropical beaches.

The Green Turtle is especially relished for its meat and for making soup, while the eggs are considered a delicacy. It has long been exploited by indigenous peoples, who are now threatened with the loss of a legitimate natural resource if over-exploitation is not curbed. WWF and IUCN have channeled considerable funds into scientific research and conservation measures for the marine turtles, including support for an international group of specialists to coordinate the work.*
